This report was submitted by The Aerospace Corporation, El Segundo, CA 90245-4691, under Contract No. F04701-88-C-0089 with the Space Systems Division, P. O. Box 92960, Los Angeles, CA 90009-2960. It was reviewed and approved for The Aerospace Corporation by J. M. Straus, Principal Director, Communications Systems Subdivision.

Seth Parkoff, Capt, USAF, was the project officer for the Mission-Oriented Investigation and Experimentation (MOIE) program. This report has been reviewed by the Public Affairs Office (PAS) and is releasable to the National Technical Information Service (NTIS). At NTIS, it will be available to the general public, including foreign nationals.

This technical report has been reviewed and is approved for publication. Publication of this report does not constitute Air Force approval of the report's findings or conclusions. It is published only for the exchange and stimulation of ideas.

19. ABSTRACT (Continue on reverse if necessary and identify by block number)  An algorithm is presented for plotting antenna and scattering patterns in three dimensions on video displays or laser printers. The algorithm exploits the property of single-valued surfaces to allow the implicit removal of hidden lines with virtually no extra computation. This reduces the computation time significantly over that required by more general surface-representation methods. The algorithm is flexible enough to implement on most graphic systems. Simple language-independent pseudo-code is presented and tested for functions in rectangular, cylindrical, and spherical coordinates.

## I. Introduction

The representation of antenna and scattering patterns in three dimensions provides a useful tool for analyzing power flow or field strength, especially when used in conjunction with field line contour plots (Ref. 1). Geometrically, these patterns represent surfaces. A comprehensive bibliography of surface-representation algorithms is given by Griffiths (Ref. 2). Most of these algorithms are geared towards representing the complex shape of a physical object. Specific algorithms for plotting mathematical functions of two variables in rectangular coordinates generally follow the method proposed by Wright (Ref. 3). Advanced line drawing algorithms suitable for cylindrical and spherical coordinates have been developed by Scott (Ref. 4). Unfortunately, all these methods require a significant amount of additional computation to be able to plot the surface with the hidden lines removed. The algorithm developed and presented in this paper avoids this extra computation by exploiting known properties of the surfaces being plotted.

In general, line drawing algorithms do not remove hidden lines, but rather, simply do not draw them. An alternative way to remove the hidden lines of a surface is to paint over the hidden part with the same color as the background. This is exactly the technique an artist would use to paint a landscape. The image is placed on the viewing surface from background to foreground and hidden lines are painted over. Of course, this requires the graphics system to be able to fill or erase a polygonal region. Therefore, the algorithm proposed in this paper is not suitable for representing surfaces by means of mechanical pen plotters. However, it is ideally suited for video displays and laser printers.

The algorithm is based on the following postulate. If a function  $f(u, v)$ , where  $u$  and  $v$  are two coordinates of an orthogonal system, generates a single-valued surface in the variables  $u$  and  $v$ , then, there exists a systematic, although not unique, ordered sequence in which to draw the surface from

back to front. This sequence is known, a priori, once the observation angles are specified. Therefore, no hidden line removal is necessary. Thus, plotting a function with the hidden lines removed takes the same amount of time as plotting without removing the hidden lines. A single-valued surface is defined as a surface in which there is a one to one correspondence between each pair of coordinates  $(u, v)$  and a point on the surface. Aperture distributions, antenna patterns, and scattering patterns are known to generate surfaces that are single-valued with respect to a particular coordinate system.

## II. Coordinate Systems

The functions of interest in this study are plotted in rectangular, cylindrical, and spherical coordinates. The standard variables that describe these coordinate systems are defined by

$$r = \sqrt{x^2 + y^2} \quad (1)$$

$$R = \sqrt{r^2 + z^2} \quad (2)$$

$$\phi = \tan^{-1}(y/x) \quad (3)$$

$$\theta = \tan^{-1}(r/z). \quad (4)$$

In order to organize the algorithm inputs consistently, let  $f(u, v)$  describe a function of two variables from one of these coordinate systems. Table 1 shows the convention adopted for the relationship between  $u$  and  $v$  and the standard variables. Since the final plot is placed on a two-dimensional surface, it is convenient to perform this step in rectangular coordinates. Therefore, all plotting points will be converted to rectangular coordinates prior to any drawing. The conversion conventions are shown in Table 2. Once the points on the surface are converted to rectangular coordinates, the graphical operations of scale, rotation, and projection may be applied.

Table 1. Variable Definitions

	rectangular	cylindrical		spherical
$u$	$x$	$\phi$	$\phi$	$\phi$
$v$	$y$	$r$	$z$	$\theta$

Table 2. Conversions to Rectangular Coordinates

	rectangular	cylindrical		spherical
$x$	$u$	$v \cos u$	$f(u, v) \cos u$	$f(u, v) \sin v \cos u$
$y$	$v$	$v \sin u$	$f(u, v) \sin u$	$f(u, v) \sin v \sin u$
$z$	$f(u, v)$	$f(u, v)$	$v$	$f(u, v) \cos v$

### III. Scale, Rotation, and Projection

The surface defined by  $f(u, v)$  is represented by the graphical transformations of scale, rotation and projection. Each graphical operation must be applied to individual coordinates of the surface. Let each point of the surface be defined by the vector  $w$  such that

$$w = \begin{bmatrix} x \\ y \\ z \end{bmatrix}. \quad (5)$$

The graphical operations may now be defined as matrices that operate on this vector.

In order to enhance some visual attributes, it may be desirable to scale each point before plotting. A scaling matrix  $S$  is defined as

$$S = \begin{bmatrix} S_x & 0 & 0 \\ 0 & S_y & 0 \\ 0 & 0 & S_z \end{bmatrix} \quad (6)$$

where each component is some specified constant. Note that to preserve the linearity of the scale, the condition  $S_x = S_y$  must be satisfied in cylindrical coordinates and  $S_x = S_y = S_z$  must be satisfied in spherical coordinates. The coordinate points are then scaled by forming the matrix vector product  $Sw$ . Another type of scaling, which is quite commonly used in plotting antenna and scattering patterns, involves converting the function to decibels. This allows the viewer to observe more detail of the sidelobe behavior. Let  $f$  be normalized to the range  $0 \leq f \leq 1$ . Then define the zero reference in dB as  $\nu$ . Next, define a plot floor level in dB as  $\eta$ , such that  $\eta \geq \nu$ . This plot floor is the level to which the function is set to for any value below the floor. This avoids a cluttered graph that results from too many low-level sidelobes. The function  $f$  can then be converted to a dB scale such that  $0 \leq f_{dB} \leq 1$  by the nonlinear transformation

$$f_{dB} = \begin{cases} \frac{1}{|\nu|}(\eta + |\nu|) & f \leq 10^{(\eta/10)} \\ \frac{1}{|\nu|}(10 \log(f) + |\nu|) & f > 10^{(\eta/10)}. \end{cases} \quad (7)$$

The observer is assumed to be stationary, so the surface of the function must be rotated to the correct view. Viewing any finite three-dimensional object requires a minimum of one rotation axis. However, it is usually necessary to have rotation around two axes. These axes should be perpendicular to allow the widest range of viewing angles. The convention adopted in this study is to allow an azimuthal rotation around the  $z$  axis and an elevation rotation in the  $yz$  plane. This is convenient for plotting antenna patterns, aperture distributions and scattering patterns. The visual result is a graph that appears to spin in azimuth around the  $z$  axis and is tipped in elevation toward or away from the viewer.

It is important to distinguish between the observation angles and the rotation angles. The viewer-supplied elevation observation angle is defined as  $\theta_0$ , and the azimuth observation angle is defined as  $\phi_0$ . These angles will be restricted to the ranges  $0 \leq \theta_0 \leq \pi$  and  $0 \leq \phi_0 \leq 2\pi$ , respectively. The use of these angles provides viewers a familiar frame of reference. In order to view the surface from these angles, it is necessary to define an azimuth rotation angle  $\alpha$  and an elevation rotation angle  $\beta$ . These angles are dependent on the observation angles and the orientation of the viewer to the rectangular coordinate system. It is assumed that the observer will look in from the positive  $z$  axis onto the  $xy$  plane. The  $x$  axis increases from left to right and the  $y$  axis increases from bottom to top. Once this convention is established and the observation angles are specified, the rotation angles can be calculated as

$$\alpha = -\frac{\pi}{2} - \phi_0 \quad (8)$$

$$\beta = \theta_0. \quad (9)$$

The order of rotation is not commutative. The plots must first be spun in azimuth by the angle  $\alpha$  and then tipped in elevation by the angle  $\beta$ . Reversing the order would allow the plot to tip from side to side, which presents an awkward picture. The azimuth rotation in the  $xy$  plane is represented by the

matrix vector product  $R_\alpha \mathbf{w}$ , where

$$R_\alpha = \begin{bmatrix} \cos \alpha & -\sin \alpha & 0 \\ \sin \alpha & \cos \alpha & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (10)$$

and the elevation rotation in the  $yz$  plane by the product  $R_\beta \mathbf{w}$ , where

$$R_\beta = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \cos \beta & \sin \beta \\ 0 & -\sin \beta & \cos \beta \end{bmatrix}. \quad (11)$$

The complete transformation can be represented by the matrix  $T$ , defined by

$$T = R_\beta R_\alpha S. \quad (12)$$

If  $\mathbf{w}'$  represents the transformed coordinates then

$$\mathbf{w}' = T\mathbf{w}. \quad (13)$$

Viewing a three-dimensional plot on a two-dimensional surface requires a projection of the three-dimensional coordinate points onto a two-dimensional viewing plane. Perspective projection implies that the further a point is away from the viewer, the smaller it appears. This type of projection is appropriate for images that evoke a strong depth cue such as a building or a landscape. However, mathematical functions do not require a strong depth cue since there is no physical object being represented. Therefore, it is sufficient to project each point along a parallel line until it intercepts the viewing plane. This type of projection is called parallel projection. Using parallel projection implies that only the  $x'$  and  $y'$  components of the vector  $\mathbf{w}$  are needed to represent the surface. The  $z'$  coordinate represents the depth of each point and is not used.

These three graphical transformations are independent of the type of function being plotted. They represent the transformation of a point on the function surface to a point on the viewing surface. The order in which points are operated on by the transformation is determined by the sequencing algorithm discussed in the next section.

## IV. Algorithm Description

The proposed algorithm is based on the generic "painter's algorithm." This concept means that the surface of the plot is rendered by building up the image from back to front. Since the function has two variables, the surface is most naturally described by a collection of quadrilaterals. Each quadrilateral is placed on the viewing surface and is painted with the background color of the surface. A line around the perimeter is then drawn. The key, of course, is to know the order in which to place the quadrilaterals on the viewing surface. A previous method, developed by the author (Ref. 5), used the transformed  $z$  coordinate of the centroid of each quadrilateral and sorted by depth. This method was general enough to plot any surface. However, the time required to compute the depth of each centroid and to sort the values led to a significant time delay. The new method proposed avoids this delay by drawing in a prescribed order based on the observation angles  $\phi_0$  and  $\theta_0$ .

The variables  $u$  and  $v$  are discretized such that  $u = u_m$  for  $m = 1 \dots N_u$  and  $v = v_n$  for  $n = 1 \dots N_v$ . By convention, the values sequence from the minimum to the maximum values. The function  $f(u, v)$  is then sampled at the discrete points  $f_{m,n} = f(u_m, v_n)$ . Each quadrilateral has a reference corner that has index values  $(m, n)$ . The other three corners are dependent on these indices and are given by  $(m+1, n)$ ,  $(m+1, n+1)$ , and  $(m, n+1)$ . It should be noted that the definition of a quadrilateral is extended to allow any number of corners to have the same location. Therefore, a point, a line, and a triangle, can also be represented by a quadrilateral. The crux of the algorithm is to find a systematic method of sequencing through the indices in order to approximate a back-to-front ordering. The sequencing orders presented for the three coordinate systems analyzed were chosen based on ease of programming.

## V. Rectangular Coordinates

Rectangular coordinates are the most common way of representing patterns in three dimensions. The coordinates  $x$  and  $y$  are replaced by  $\phi$  and  $\theta$ . Assume for simplicity that the coordinates are translated so that the origin is in the interior of the range. This does not affect the generality of the algorithm, but merely the presentation. Since the function is plotted on a rectangular base, it may be surmised that one corner of the surface will always be nearest to the observer and the opposite corner will be the farthest away. Because of the rotation conventions used, this is dependent only on the azimuth observation angle  $\phi_0$  and independent of the elevation observation angle  $\theta_0$ . Therefore, the first part of the algorithm determines which corner is nearest to the observer. Once the orientation is established, the quadrilaterals are simply drawn from the back corner to the front corner by rows that alternate in direction. Alternating the rows helps to move forward in a more uniform manner. Figure 1 shows the drawing directions as the quadrilaterals are placed on the viewing surface from back to front. Note that at the angles  $0^\circ$ ,  $90^\circ$ ,  $180^\circ$ ,  $270^\circ$  and  $360^\circ$  there are two back corners equidistant from the viewer. In this case, it does not matter which corner is chosen as long as it is chosen consistently. Figure 2 shows the far-field power pattern of a uniformly excited square aperture plotted at observation angles  $\phi_0 = 30^\circ$  and  $\theta_0 = 60^\circ$ . The plotting algorithm used is given in pseudo-code as follows:

```

M = minimum of ( $N_u, N_v$ )
if  $0 \leq \phi_0 < \pi/2$  then {find nearest corner}
     $i = 1, j = 1$ 
else if  $\pi/2 \leq \phi_0 < \pi$  then
     $i = -1, j = 1$ 
else if  $\pi \leq \phi_0 < 3\pi/2$  then
     $i = -1, j = -1$ 
else if  $3\pi/2 \leq \phi_0 \leq 2\pi$  then
     $i = 1, j = -1$ 
end if
loop from  $l = 1$  to  $M - 1$ 
    if  $0 \leq \phi_0 < \pi/2$  then {find nearest corner}

```

## VI. Cylindrical Coordinates

Cylindrical coordinate functions of the form  $z = f(\phi, r)$  and  $r = f(\phi, z)$  are commonly encountered in antenna and scattering analysis. Far-field patterns can be plotted in the coordinates  $f(\phi, r)$  by letting  $r = \theta$ . This type of plot is good for observing the finer details of the sidelobe structure. It is also a natural way to plot circular aperture distributions. Alternatively, functions of the form  $r = f(\phi, z)$  are useful for observing near-field patterns or surface currents on structures such as a cylinder or a body of revolution.

Cylindrical functions of the form  $z = f(\phi, r)$  are plotted on a circular base with a specified foreground angle  $\phi_0$  and a background angle  $\phi_a = \phi_0 \pm \pi$ , chosen such that  $0 \leq \phi_a \leq 2\pi$ . Therefore, the  $\phi$  dependency of the quadrilaterals should be drawn starting with the background angle  $\phi_a$  and proceeding toward the foreground observation angle  $\phi_0$ . The method employed is to find the index  $m$  of the  $u_m$  nearest to  $\phi_a$  and then alternately increase and decrease the value to draw from back to front. For simplicity, assume that  $u_{min} = 0$  and  $u_{max} = 2\pi$ . Since  $\phi$  is periodic, the index  $m$  must be periodic with period  $N_u - 1$ . Drawing the radial dependence from back to front is dependent on the value of  $\phi$ . Observation of the drawing flow pattern in Fig. 3 shows that the radial dependence should be drawn from  $r_{max}$  to  $r_{min}$  when the angle  $u_m$  is greater than  $90^\circ$  from  $\phi_0$ , and from  $r_{min}$  to  $r_{max}$  when the angle is less than  $90^\circ$  from  $\phi_0$ . Figure 4 shows the power pattern of a uniformly excited square aperture plotted in dB, with  $\nu = -40$  dB and  $\eta = -25$  dB. In some plotting situations it is desirable to remove an angular sector, to allow better viewing of the surface. This can be easily accomplished because of the way the  $\phi$  values are alternated when plotting. Defining  $N_s$  as the number of segments to remove, the total number of  $\phi$  values is just reduced by that amount. Figure 5 illustrates the use of angular cuts in a plot of the magnitude of the far-field electric field of a uniformly excited circular aperture. The following pseudo-code implements the algorithm:

Fig. 3. Drawing flow pattern for cylindrical coordinates

Fig. 4. Power pattern of uniformly excited square aperture viewed from  $\theta_0 = 60^\circ$  and  $\phi_0 = 30^\circ$  and plotted in dB, with  $\nu = -40$  dB and  $\eta = -25$  dB

Fig. 5. Magnitude of far-field electric field of a uniformly excited circular aperture viewed from  $\theta_0 = 50^\circ$  and  $\phi_0 = 30^\circ$  and plotted in dB, with  $N_r = 14$ ,  $\nu = -40$  dB and  $\eta = -25$  dB

```

loop from  $k = 1$  to  $N_u - 1$  {find index of angle  $\phi_a$ }
  if  $\phi_a \geq u_k$  and  $\phi_a \leq u_{k+1}$  then
     $m = k$ 
  end if
continue  $k$  loop
loop from  $l = 1$  to  $N_u - N_s - 1$ 
   $m = m - (-1)^l(l - 1)$ 
  if  $(m < 1)$  then {force index to be periodic}
     $m = m + N_u - 1$ 
  else if  $(m > N_u - 1)$  then
     $m = m - (N_u - 1)$ 
  end if
  if  $|u_m - \phi_0| < \pi/2$  or  $|u_m - \phi_0| > 3\pi/2$  then
     $n_0 = 0, \quad i = 1$  {draw from  $r_{min}$  to  $r_{max}$ }
  else
     $n_0 = N_v, \quad i = -1$  {draw from  $r_{max}$  to  $r_{min}$ }
  end if
  loop from  $k = 1$  to  $N_v - 1$ 
     $n = n_0 + ik$ 
    {get  $(u_m, v_n)$  and other 3 corners }
    {convert to rectangular coordinates - Table 2 }
    {scale, rotate, and project using Eqn. (13)}
    {fill quadrilateral, then draw perimeter }
  continue  $k$  loop
continue  $l$  loop

```

The algorithm for plotting functions of the form  $r = f(\phi, z)$  uses the same procedure for handling the  $\phi$  variation. The  $z$  variation is handled very easily by simply noting that if the observation angle  $\theta_0$  is less than or equal to  $90^\circ$ , then draw from  $z_{min}$  to  $z_{max}$ . Otherwise, if  $\theta_0$  is greater than  $90^\circ$ , then draw from  $z_{max}$  to  $z_{min}$ . Figure 6 shows a section of circular waveguide and the magnitude of the longitudinal surface current induced on the inner walls for the  $TM_{21}$  mode. The pseudo-code for the algorithm is given as follows:

```

loop from  $k = 1$  to  $N_u - 1$  {find index of angle  $\phi_a$ }
  if  $\phi_a \geq u_k$  and  $\phi_a \leq u_{k+1}$  then
     $m_a = k$ 
  end if
continue  $k$  loop
loop from  $k = 1$  to  $N_v - 1$ 
  if  $\theta_0 \leq \pi/2$  then
     $n = k$  {draw from  $z_{min}$  to  $z_{max}$ }
  else
     $n = N_v - k$  {draw from  $z_{max}$  to  $z_{min}$ }
  end if
   $m = m_a$ 

```

Fig. 6. Circular waveguide and magnitude of surface current induced on inside wall

```

loop from  $l = 1$  to  $N_u - N_s - 1$ 
   $m = m - (-1)^l(l - 1)$ 
  if  $(m < 1)$  then {force index to be periodic}
     $m = m + N_u - 1$ 
  else if  $(m > N_u - 1)$  then
     $m = m - (N_u - 1)$ 
  end if
  {get  $(u_m, v_n)$  and other 3 corners }
  {convert to rectangular coordinates - Table 2 }
  {scale, rotate, and project using Eqn. (13)}
  {fill quadrilateral, then draw perimeter }
continue  $l$  loop
continue  $k$  loop

```

## VII. Spherical Coordinates

The flow of power in far-field antenna and scattering patterns is best described by using plots in spherical coordinates. Establishing the front and back orientation requires knowledge of both observation angles. The azimuth background angle  $\phi_a$  is defined the same as in cylindrical coordinates. Therefore, the  $\phi$  variation is drawn in exactly the same way as for cylindrical plots. The elevation background angle is defined as  $\theta_a = \pi - \theta_0$ . As shown in Fig. 7, the elevation dependence is drawn in opposite directions away from  $\theta_a$  when  $u_m$  is greater than  $90^\circ$  from  $\phi_0$ . When  $u_m$  is less than  $90^\circ$  from  $\phi_0$ , the elevation dependence is drawn from the minimum and maximum limits to  $\theta_0$ . Figure 8 shows a power pattern of a circular aperture plotted in dB with  $\nu = \eta = -60$  dB. As with cylindrical coordinates, it is sometimes convenient to cut away an angular piece of the plot so that the detail of the sidelobe pattern may be observed. However, since the lobes of spherical plots are generally closed surfaces, it looks better if the angular cut is filled with the background color. This is illustrated in Fig. 9. Filling this cut requires making a polygon using all the  $\theta$  values at a constant  $\phi$ . The following pseudo-code implements the algorithm:

```

loop from  $k = 1$  to  $N_u - 1$  {find index of angles  $\phi_0, \phi_a$ }
  if  $\phi_0 \geq u_k$  and  $\phi_0 \leq u_{k+1}$  then
     $m_0 = k$ 
  end if
  if  $\phi_a \geq u_k$  and  $\phi_a \leq u_{k+1}$  then
     $m_a = k$ 
  end if
continue  $k$  loop
 $n_0 = N_v$     $n_a = N_v$ 
loop from  $k = 1$  to  $N_v - 1$  {find index of angles  $\theta_0, \theta_a$ }
  if  $\theta_0 \geq v_k$  and  $\theta_0 \leq v_{k+1}$  then
     $n_0 = k$ 
  end if
  if  $\theta_a \geq v_k$  and  $\theta_a \leq v_{k+1}$  then
     $n_a = k$ 
  end if
continue  $k$  loop
 $m = m_a$ 

```

Fig. 7. Elevation dependence drawing pattern for spherical coordinates

Fig. 8. Power pattern of uniformly excited circular aperture viewed from  $\theta_0 = 60^\circ$  and  $\phi_0 = 30^\circ$

Fig. 9. Power pattern of uniformly excited circular aperture viewed from  $\theta_0 = 60^\circ$  and  $\phi_0 = 30^\circ$

```

loop from  $l = 1$  to  $N_u - N_s - 1$ 
   $m = m - (-1)^l(l - 1)$ 
  if  $(m < 1)$  then {force index to be periodic}
     $m = m + N_u - 1$ 
  else if  $(m > N_u - 1)$  then
     $m = m - (N_u - 1)$ 
  end if
  if  $|u_m - \phi_0| < \pi/2$  or  $|u_m - \phi_0| > 3\pi/2$  then
     $i = N_v, j = 0, L_1 = N_v - n_0, L_2 = n_0 - 1$ 
  else
     $i = M_a, j = n_a - 1, L_1 = n_a - 1, L_2 = N_v - n_a$ 
  end if
  loop from  $k = 1$  to  $L_1$ 
     $n = i - k$ 
    { get  $(u_m, v_n)$  and other 3 corners }
    { convert to rectangular coordinates - Table 2 }
    { scale, rotate, and project using Eqn. (13)}
    { fill quadrilateral, then draw perimeter }
  continue  $k$  loop
  loop from  $k = 1$  to  $L_2$ 
     $n = j + k$ 
    { get  $(u_m, v_n)$  and other 3 corners }
    { convert to rectangular coordinates - Table 2 }
    { scale, rotate, and project using Eqn. (13)}
    { fill quadrilateral, then draw perimeter }
  continue  $k$  loop
  if  $l > N_u - N_s - 3$  and  $N_s > 0$  then
    if  $u_m \geq \phi_0$  then
      if  $(u_m \geq \phi_0$  and  $u_m \leq \phi_a)$  then
         $p = m$ 
      else
         $p = m + 1$ 
      end if
    else
      if  $(u_m \geq \phi_a$  and  $u_m \leq \phi_0)$  then
         $p = m + 1$ 
      else
         $p = m$ 
      end if
    loop from  $q = 1$  to  $N_v$ 
      { form polygon with vertices  $(u_p, v_q)$  }
    continue  $q$  loop
    { fill polygon, then draw perimeter }
  end if
continue  $l$  loop

```

## VIII. Conclusion

An algorithm has been presented that allows the rapid plotting of antenna and scattering patterns in three dimensions. Because of the special properties of the types of functions considered, the plotting speed is essentially the same as if no hidden lines were removed. Any graphics system that allows a polygon fill operation may implement the algorithm. Although not suitable for mechanical pen plotters, the algorithm is ideal for video displays and laser printers. The specific variations in rectangular, cylindrical, and spherical coordinates have been developed and tested yielding excellent results.

## Appendix: Fortran 77 Programs

This appendix contains the Fortran 77 programs RECT3D, CYLA3D, CYLR3D, and SPHR3D as well as all associated subroutines. The required inputs to each program are listed in the comments found in the source code. These programs were used to generate all the results presented in this report. The output of each program is a PostScript file. Information on programming in the PostScript language is available from most bookstores.
